Abstract
A common and conspicuous member of the medusan fauna of South Africa has been the subject of repeated taxonomic confusion. After having been mistakenly identified by earlier workers as either Carybdea alata or Tamoya haplonema, this large and colourful carybdeid is described herein as Carybdea branchi, sp. nov. It is distinguished from its congeners on numerous characters: body to about 8cm in life, densely scattered with nematocyst warts over the whole body and abaxial keels of the pedalia; a bulge or lateral thorn on the pedalial canal bend; with 2 dendritic velarial canals per octant, highly diverticulated; with a long manubrium; with greatly bushy epaulette-like phacellae, comprising 20 or more roots tightly clustered; with well developed mesenteries; and with conspicuous brownish pigmented areas over the proximal and distal regions of the pedalia and over the phacellae. A comparative table of the primary diagnostic characters of species in the genus Carybdea is given.

Keywords Carybdeida, Carybdeidae, medusae, taxonomy, Cape Town, new species, marine stinger

Introduction
Very few references exist on the carybdeids in African waters. Species occurring there have typically been attributed to well known species from elsewhere, rather than being recognised for their unique morphology. Haeckel (1880), Uchida (1970), and Branch et al. (1994) reported "Carybdea alata" (= Alatina alata (Reynaud, 1830), see Gershwin 2005b) off South Africa, while Stiasny (1939) reported it off West Africa. From Uchida's (1970) description, it seems quite likely that his specimen is referable to the species described below rather than to the true A. alata.

Haeckel (1880) described Carybdea murrayana from West Africa. Mayer (1910), Bigelow (1938), and Kramp (1961) considered C. murrayana to be conspecific with C. marsupialis. However, recent studies suggest otherwise (Gershwin 2005a).

Ranson (1945) reported Carybdea marsupialis (Linnaeus, 1758) off Algiers, North Africa; it is currently unclear if this report may be referable to C. murrayana, or even possibly to the new species described herein; the range limits of these two species are not yet known.
*Tamoya haplonema* Muller (1859) was reported in African waters by Stiasny (1934), Ranson (1949), Kramp (1955; 1959), and Pages et al. (1992). That species is common along western Atlantic shores from Argentina to New York, and is immediately identifiable in having vertical phacellae with the cirri in bands along the perradial sides of the bag-like stomach.

A large and colourful species of *Carybdea* is common along South African shores, but has been hitherto overlooked as being new to science. The purpose of our paper is to describe this new species of box jellyfish, and in doing so, to rectify some of the mistakes that have been made historically relating to the species.

**Materials and methods**

The material described herein was collected from the east and south coasts of South Africa. Material was fixed in 5-10% formalin in seawater. All taxonomic observations and measurements were made on preserved material unless otherwise noted. Measurements were made with Max-Cal digital calipers to the nearest 0.01mm. Bell height (BH) was measured from the apex of the bell to the velarial turnover. Diagonal bell width (DBW) was measured across diagonal pedalia on a flattened specimen, at the height where the pedalium joins the exumbrella of the bell. Interrhopalial width (IRW) was measured between adjacent rhopalia, with the specimen flattened. Tentacle base width (TBW) was measured at the uppermost part of the tentacle, immediately below the pedalium; if the tentacle was flattened, width was measured across the widest points. In opaque specimens, phacellae were studied by making a small incision in the upper corners of the bell, and then pulling back a small amount of mesoglea to expose the floor of the stomach, or by opening up the full length of the body wall to expose the stomach, and then opening the stomach in the same manner. In transparent specimens, phacellae were obvious. Nematocysts were examined and measured with a Leica DMLB compound microscope and Leica IM-50 Image Manager v. 1.20 for Windows; all observations and photographs were made under 400x magnification. Nematocysts were identified following the keys of Calder (1974), Mariscal (1971), Williamson et al. (1996), and Gershwin (2006).

**Abbreviations used.** South African Museum, Cape Town (SAMCT); Natural History Museum, London (NHM); Nationaal Natuurhistorisch Museum, Naturalis, Leiden (NNM); South Australian Museum, Adelaide (SAMA); and Zoological Museum, University of Copenhagen (ZMUC). SAMCT H4866, same loc. as holotype but collected 17 January 2001, by L. Gershwin & G. Branch; 6 specimens: A) 52.83 mm BH, 70.90 mm DBW, 32.51 mm IRW; B) 47.75 mm BH, 59.46 mm DBW, 30.93 mm IRW; C)
42.64 mm BH, 54.41 mm DBW, 26.67 mm IRW; D) 44.79 mm BH, 55.09 mm DBW, 28.86 mm IRW; E) 42.24 mm BH, 53.47 mm DBW, 30.02 mm IRW; F) 33.26 mm BH, 40.43 mm DBW, 18.49 mm IRW, 27.90 mm rhopalium to apex, 2.89 mm TBW, 17.85 mm outer pedalial length. ZMUC unnumb., False Bay, coll. Papenfuss, "Africana"; 48.56 mm BH.

**Type locality.** Albert Basin, Victoria & Albert Waterfront, Cape Town, South Africa.

**Diagnosis.** Carybdea with a large, robust, well sculptured body; nematocyst warts densely scattered over whole body and abaxial keels of pedalia, lacking on adaxial keels; adaxial pedalial keels broadly rounded; bend of pedalial canal with a bulge or lateral thorn; velarial canals 2 per octant, dendritic, highly diverticulated; manubrium long; phacellae greatly bushy; mesenteries well developed; brownish pigmented areas conspicuous over proximal and distal regions of pedalia, as well as over phacellae.

**Description.** Bell to about 68 mm in height (after several days in formalin), about 80 mm live (Plate 1A), with thick, rigid mesoglea, especially apically; with numerous oblong to amorphous small unraised or slightly raised nematocyst warts scattered densely over entire exumbrella (Plate 1B). Coronal indentation shallow just below apex (Plate 1A). Interradius thickened throughout bell height, with deep median furrow reaching all the way to pedalium. Adradial furrows strongly pronounced, deeper in lower half of bell (Plate 2A). Perradius smooth, raised, with rhopalial niche surrounded by deep horseshoe-shaped furrow (Plate 2A).

Sensory niches 4, perradial, heart-shaped (Plate 2B), with 1 shallow covering scale above and 2 nearly imperceptible scales below; located approximately 1/6 BH from velarial turnover; lacking "rhopalial horns". Subumbrellar rhopalial windows shallowly convex, with a small concavity marking junction with rhopalial stalk. Eyes 6 per rhopalium, 2 median lensed eyes plus 4 lateral pigmented eye spots. Rhopalial warts lacking. Statolith shape unknown.

Pedalia about 1/2 bell height (Plate 1A, B); outer keel densely covered with low nematocyst warts (Plate 2C), flared from body at junction, such that outer edge of pedalial canal is even with outer body wall, with pedalial keel projecting several mm beyond; inner keel greatly rounded, nearly hemispherical; without tentacular overhang. Pedalial canal strongly quadratic in cross section throughout length, flared slightly at tentacle insertion; outer portion of bend with broadly rounded bulge or lateral-pointing thorn.
PLATE 1. Carybdea branchi, sp. nov., holotype, live, lateral view. A. In situ. B. In laboratory. Bell height approximately 80 mm live, 68 mm preserved in 5-10% formalin.
Tentacles 4, with 1 per pedalium; base to about 6 mm thick, round or flattened somewhat in cross section, gradually tapering distally (Plate 1A); with nematocyst rings all of equal size.

Velarium narrow, lacking nematocyst warts or freckles. Velarial canals 2 per octant, dendritic (Plate 2D), with edges of branches bearing lateral lobations, non-anastomosing. Perradial lappets absent. Frenulum narrowly developed, comprising a single solid gelatinous cord-like strip of tissue, extending only about 3/4 distance to velarial margin.
PLATE 3 A. Carybdea branchi, sp. nov., phacella lifted up from stomach (Paratype SAMA A376); note a primary stalk visible at midline, and another behind it. B. Carybdea branchi, sp. nov., phacella dissected out from stomach (Paratype NNM 5228); note numerous primary stalks attached to body as a single bundle. C-F. Carybdeid phacellae forms, indicated with arrows, as viewed without dissection: epaulette-form (C, C. marsupialis); linear horizontal (D, C. rastonii, image by I. Bennett); crescentic horizontal (E, Alatina rainensis); linear vertical (F, Tamoya haplonema, image by A. Migotto). G. Crescentic phacella in situ with bell wall peeled away, Alatina mordens.

Stomach flat. Manubrium long, with large, narrowly rounded lips (Plate 2E) reaching to at least halfway down bell cavity in life. Mesenteries flap-like halfway to rhopalium, with cord-like extension to rhopalium. Phacellae (Plate 3A, B) greatly bushy, arising from up to about 20 closely pressed stalks in a single tight bundle; each stalk dendritically branched numerous times to endings of single or paired short, solid cirri. Gonads attached along entire length of interradial septa; narrowly leaf-shaped, typically not overlapping along the interradius in present collection, pleated or simple. Interradial septa lacking perforations.

Colour in life: slightly translucent whitish with conspicuous pigmentation comprising a single dark red blotch on abaxial corner of pedalium at base of each of the 4 tentacles (Plates 1A, B, 2C), a single small red blotch on apical portion of exumbrella above each of the four phacellae (Plate 1A), and a single faint brownish blotch at "shoulder" of each of the four pedalia (Plates 1A, 2C). Tentacles whith to faintly pinkish (Plates 1A, 2C).

Nematocysts. As detailed in Gershwin (2005a; 2006: 9, Tab. 1), the tentacular nematocysts are of two types, namely small oval isorhizas (13.39-17.62 pm x 6.06-8.20 pm, n=15), and heterotrichous microbasic euryteles (19.33-31.12 pm x 11.98-16.39 pm, n=33). There are also two types of bell nematocysts, namely, spherical isorhizas (15.53-20.64 pm, n=40), and oval ?amastigophores (15.42-16.30 pm x 9.5-11.05 pm, n=28). The nematocysts of the phacellae and manubrium were not examined.

Etymology. This species is named to honour Professor Emeritus George Branch (University of Cape Town), preeminent zoologist specialising in South African ecosystems.

Distribution. Presently known only from South Africa, from Port Elisabeth along the south coast, to Laangebaan, Soldhana Bay, on the west coast.

Stinging ability. George Branch recounted a sting event that he believed was from this species. The sting occurred around the chest, with a solid band width ca 2.5 mm. The effects were: (1) acute fire-like pain (lasting about 10 minutes), becoming progressively more tolerable as time went on; (2) cessation of heart-beat (for about 15 seconds), followed by abnormally rapid heart beats (guessing about three times the normal rate), followed by cessation of heartbeat once again, and again rapid heartbeats; after three bouts, the heart stabilized.

Whilst sting inhibitors or remedies have not been formally tested on C. branchi, prudence would suggest that this species should be treated similarly to other cubozoans until demonstrated otherwise. As such, the following first aid procedure is recommended:

Call for help if patient is in distress (ring ambulance)
Treat the patient: CPR if necessary
Treat the sting: Douse with vinegar to inhibit further envenomation, then apply ice as needed for pain
Monitor patient and seek medical attention as necessary

**Phylogeny.** Gershwin (2005a: figures 3.3, 3.4) found that *C. branchi* (as *Carybdea* n.sp. Cape Town) clustered with *C. rastonii* and *C. mora* as the sister group to the Australian form of *C. xaymacana* in both morphological and partial 18S phylogenies of many species of Cubozoa. This arrangement is surprising, given the closer general resemblance between *C. xaymacana* and *C. branchi*, compared to *C. rastonii* and *C. branchi* (see Table 1). *Carybdea mora* has long been considered identical to *C. rastonii* by most authors, but was demonstrated by Gershwin (2006) to have a distinctive cnidome. *Carybdea branchi*, *C. mora*, *C. marsupialis* and *C. xaymacana* have epaulette-like phacellae, whereas the linear horizontal phacellae in *C. rastonii* readily separate it from the others. Therefore, discordance exists between the historical morphological interpretation and the molecular and morphological phylogenies in the genus *Carybdea*. Without doubt, a more thorough phylogenetic analysis of more species and more specimens in the genus will help clarify these questions.

**Systematic remarks.** *Carybdea branchi* is distinguished from all other species of *Carybdea* in having a much larger and more robust body, and lateral digitations on the velarial canals. Of the species currently or recently recognised in the genus, *Carybdea branchi* is most similar to *C. marsupialis*, *C. mora*, *C. murrayana*, and *C. xaymacana* based on the shared characters of heart-shaped rhopaliar niches and tightly-clustered, epaulette-like phacellae in each corner of the stomach. However, all five species are easily separated from one another on the number and form of their velarial canals, which are only two per octant and highly dendritic in *C. branchi* and *C. mora* (the former bearing diverticulations), simpler and numbering 3-4 per octant in *C. marsupialis*, six per octant in *C. murrayana*, and only two per octant, but of two types in *C. xaymacana*. Furthermore, in both *C. mora* and *C. branchi* the bell is evenly scattered with conspicuous nematocyst warts, rather than having them concentrated on the interradii as in other species; however, in *C. mora* the warts are in very small clusters compared to those of *C. branchi*. *Carybdea murrayana* appears to lack exumbrellar nematocysts. A comparison of primary diagnostic characters is presented in Table 1.
### TABLE 1. Comparison of primary diagnostic characters in the genus *Carybdea*. Data from original descriptions, examination of type material or new material from type locality where possible, and Gershwin (2005a; 2006b).

</table>
Whilst Uchida (1970) apparently confused *C. branchi* for *Alatina alata* (as *Carybdea*), the former is quite distinctive from the latter. For example, the rhopaliar niche ostia of *Alatina* are strongly T-shaped (with well developed lateral covering scales), whereas they are typically heart-shaped in *C. branchi* (Plate 2A; with modestly developed lateral covering scales); even in a case such as that in Plate 2B, in which the niches of *C. branchi* are somewhat T-shaped, the species would still be immediately distinguished on the basis of the gastric cirri. In *Alatina*, the cirri are very long and nestled in a parallel fashion in a crescentic row across each interradius (Plate 3G), rather than the many-rooted dendritic tuft in *C. branchi*. From Uchida's (1970: 291-293) description, it seems quite likely that the specimen in question is referable to *C. branchi* rather than to *A. alata*.
As mentioned above, *C. murrayana* from West Africa could be superficially confused with *C. branchi*, because both are relatively large carybdeids from Africa, but the velarial canals quickly separate them: in *C. branchi* the sidewalls of the canals bear many lateral digitations, whereas these are lacking in *C. murrayana*. Moreover, *C. murrayana* has many more canals at the velarial turnover (6 per octant, versus 2) but fewer branches after (about 10 tips reaching velarial margin in *C. murrayana*; but less than 10 reaching margin in *C. branchi*). Mayer (1910), Bigelow (1938), and Kramp (1961) considered *C. murrayana* to be conspecific with *C. marsupialis*.

Ranson (1945) and Kramp (1955) reported *C. marsupialis* off North Africa and *Tamoaya haplonema* off West Africa, respectively; it is currently unclear if these reports may be referable to *C. murrayana*, or even possibly to *C. branchi*. Although the range limits of these two species are not yet known, it seems plausible that the northern hemisphere/tropical reports of *C. marsupialis* and *T. haplonema* are not referable to the subtropical/cold temperate southern hemisphere *C. branchi*.

Pages et al. (1992: 57-58) curiously reported a specimen from South Africa identified as *Tamoaya haplonema*. We were unable to examine their figured specimen, but based on the description and illustrations, it seems apparent that they observed *C. branchi*. The colouration alone is quite distinctive, but perhaps this was overlooked in preservation, which bleaches the colour markings. However, they described the phacellae as being vertical, but they probably failed to appreciate how vertical the phacellae are in the true *T. haplonema*. In *T. haplonema*, the phacellae root-regions are spread out over a long, vertical region along the sides of the bag-like stomach, in a field maybe five times as high as wide, such that the cirri are not plainly visible through the top of the body (Plate 3F), but must be observed through the side wall or by dissection. In contrast, in *C. branchi* the phacellae root-regions are tightly clustered in small clumps in each corner of the stomach, plainly visible through the top of the bell without dissection. Carybdeid phacellae take numerous forms (Gershwin, 2005a: 43, and references therein), as illustrated in Plate 3: linear horizontal (e.g., *C. rastonii*), linear vertical (e.g., *Tamoaya haplonema*), crescentic horizontal (e.g., *Alatina* spp.), epaulette (e.g., *C. branchi*, *C. marsupialis*, *C. mora*, *C. xaymacana*), and lacking (*Carukia* spp., *Malo* spp., *Morbakka*, *Gerongia*). Carybdea branchi also differs from *Tamoaya* in numerous other structural characters, for example, the latter has frown-shaped rhopalial niche ostia, whereas in the former they are heart-shaped.

**Acknowledgments**

We are grateful to Michelle van der Merwe and Liz Hoensen of the South African Museum for their generosity of time and enthusiasm, and for helping us to access the collection; we are similarly grateful to the South Australian Museum for access to specimens and study facilities. We also thank George Branch, Elaine Robson, and the Two Oceans Aquarium for information about this species. This manuscript was improved by comments from Drs. Andre Morandini and Dale Calder, and an anonymous reviewer; we are grateful for their insights. We are indebted to Australian Biological Resources Study (Grants 20045 and 207-63) for generous travel and writing support to the senior author.
