ABSTRACT

We study synergies between H_I 21cm and H α intensity map observations, focusing on SKA1-like and SPHEREx-like surveys. We forecast how well such a combination can measure features in the angular power spectrum on the largest scales, that arise from primordial non-Gaussianity and from general relativistic effects. For the first time we consider Doppler, Sachs-Wolfe and integrated SW effects separately. We confirm that the single-tracer surveys on their own cannot detect general relativistic effects and can constrain the non-Gaussianity parameter f_{NL} only slightly better than Planck. Using the multi-tracer technique, constraints on f_{NL} can be pushed down to ~ 1 . Amongst the general relativistic effects, the Doppler term is detectable with the multi-tracer. The Sachs-Wolfe terms and the integrated SW effect are still not detectable.

Key words: cosmology; large-scale structure of the Universe, cosmological parameters, miscellaneous.

1 INTRODUCTION

There has been a growing interest in the field of line intensity mapping (IM) for cosmological measurements, such as the 3-dimensional (3D) large-scale structure of the Universe across cosmic time. Instead of resolving each individual galaxy, IM integrates over all emission inside the voxel (3D pixel). Hence, fluctuations in observed intensity come from fluctuation in the number of sources inside the voxel. Since we expect to have several galaxies in each pixel, the signal-to-noise should be higher than for standard galaxy surveys with a threshold magnitude. The technique has another advantage with respect to conventional photometric and spectroscopic galaxy surveys – one can probe larger sky areas with higher redshift resolution more speedily. The downside comes at the loss of small scale information. While galaxy surveys rely on clean galaxy number counts, i.e., either a galaxy is detected or not, IM has to deal with interloping line emission or other types of contaminants.

A lot of focus has been applied to the H_I 21cm line as a tracer of the dark matter distribution in the late Universe (Battye et al. 2004; Chang et al. 2008; Loeb & Wyithe 2008; Bharadwaj et al. 2009; Bagla et al. 2010; Seo et al. 2010; Chang et al. 2010; Ansari et al. 2012; Switzer et al. 2013; Battye et al. 2013; Bull et al. 2015). In fact, some observations have already been made (Kerp et al. 2011), with a detection in cross-correlation (Chang et al. 2010). A large-area H_I intensity mapping survey has been proposed for SKA1-MID (Santos et al. 2015) and for its precursor MeerKAT (Santos et al. 2017). An advantage of using the H_I line is that it has very little background and foreground contamination from

other lines, but there is major synchrotron contamination from our Galaxy.

Some authors have considered other lines as cosmological probes at low redshift, such as Ly α (Pullen et al. 2014), C_{II} and other far infra-red emission lines (Uzgil et al. 2014) and the CO rotation emission lines (Breysse et al. 2014). Fonseca et al. (2017b) performed a systematic study of all the lines (besides H_I) that can in principle be used for IM, including H α and fainter optical and far infra-red lines, to assess which had the best prospects for use as IM probes and to forecast which lines can provide measurements of the 3D power spectrum in the future. A more comprehensive summary of the current status of line IM is given by Kovetz et al. (2017).

Planned galaxy surveys will probe ever larger volumes of the Universe. This will deliver not only tighter and tighter constraints on the standard cosmological model, but also allow us to go further and test other features, such as primordial non-Gaussianity (PNG, via the parameter f_{NL}), which induces a scale-dependent correction to the bias of any dark matter tracer (Dalal et al. 2008; Matarrese & Verde 2008). Current Planck bounds on f_{NL} are the state of the art but do not provide a clear measurement: $f_{\text{NL}} \approx 0.8 \pm 5.0$ (Planck Collaboration et al. 2015). Future surveys should deliver improvements on CMB constraints by using the scale-dependent bias of tracers (see, e.g. Giannantonio et al. 2012; Camera et al. 2013; Camera et al. 2015c; Alonso et al. 2015a; Raccanelli et al. 2016). The first target is $\sigma(f_{\text{NL}}) < 1$, the threshold to start distinguishing between single-field and multi-field inflation (see, e.g. de Putter et al. 2017). However, the forecasts show that single-tracer surveys cannot reach this level of precision, even with a perfect experiment, because of cosmic variance.

On the ultra-large scales ($k < k_{\text{eq}}$) where the PNG signal in

* josecarlos.s.fonseca@gmail.com

IM is strongest, general relativistic (GR) effects on the observed brightness temperature (Hall et al. 2013) are also strongest. Neglecting these effects would bias measurements of f_{NL} in future surveys (Camera et al. 2015). Furthermore, it would discard additional information and potential tests on such uncharted scales. In IM, the GR effects include Doppler, Sachs-Wolfe (SW) and integrated Sachs-Wolfe (ISW) terms, whereas number counts have in addition lensing¹ and time-delay terms (Yoo 2010; Challinor & Lewis 2011; Bonvin & Durrer 2011). Several papers have studied how well future galaxy and IM surveys will be able to distinguish GR corrections from the dominant contributions to the density contrast (see e.g. Yoo et al. 2012; Alonso et al. 2015a; Camera et al. 2015; Raccanelli et al. 2016). Because of the same cosmic variance problem that limits $\sigma(f_{\text{NL}})$, GR effects (other than lensing) cannot be detected in single-tracer surveys.

Cosmic variance is indeed sampling variance of cosmological scales. Since we only have one realisation of the Universe, ever larger scales have ever less repetitions in the cosmological statistical ensemble at that scale. Despite this, a way has been proposed to beat down cosmic variance when measuring effects in tracer-dependent bias-like parameters. The multi-tracer (MT) technique to combines two or more tracers of the underlying dark matter field (Seljak 2009; McDonald & Seljak 2009; Hamaus et al. 2011; Abramo & Leonard 2013; Abramo et al. 2016) to cancel sample variance. This technique is opening up a new window on constraining and measuring ultra-large scale effects in the 3D power spectrum with next-generation surveys of the large-scale structure (Yoo et al. 2012; Ferramacho et al. 2014; Yamauchi et al. 2014; Alonso & Ferreira 2015; Fonseca et al. 2015, 2017a; Abramo & Bertacca 2017). In addition to reducing cosmic variance, the MT technique contains cross-correlations (between tracers and redshift bins) that help to reduce individual systematics and foreground/background residuals.

In this paper we consider for the first time the potential synergies between two IM surveys using the MT technique: a HI survey like the survey planned for Phase 1 of the SKA² (Maartens et al. 2015; Santos et al. 2015), and a H α survey like the survey envisaged in the proposal for SPHEREx³ (Doré et al. 2014). We investigate how the results depend on sky area and the assumed noise of the experiments, as well as the redshift resolution of the combined survey. Our forecasts show that in principle, the Doppler term can be measured at $\sim 3\sigma$, and $\sigma(f_{\text{NL}}) \sim 1$ is achievable. As we will explain, the smallness of the bias ratio of HI and H α undermines the constraining power of these two tracers on f_{NL} and GR effects.

The paper is organised as follows: in §2 we review the 3D angular power spectrum for IM, including all large-scale effects; we describe the experimental specifications of the surveys in §3; §4 reviews the Fisher forecast analysis and presents the chosen observational strategy; the results are presented in §5 and discussed in §6.

2 ANGULAR POWER SPECTRUM FOR INTENSITY MAPS

Let $\Delta^{W_A}(z_i, \mathbf{n})$ be the observed contrast of intensity or temperature fluctuations for tracer A in direction \mathbf{n} and in a redshift bin

(with window W_A) centred on z_i . We decompose each sky map in a spherical harmonic basis $Y_{\ell m}(\mathbf{n})$ and use the amplitudes $a_{\ell m}^{W_A}(z_i)$ as our observational estimator, where

$$\Delta^{W_A}(z_i, \mathbf{n}) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} a_{\ell m}^{W_A}(z_i) Y_{\ell m}(\mathbf{n}). \quad (1)$$

Since the universe is statistically homogeneous and isotropic, $\langle a_{\ell m} \rangle = 0$ at every redshift. Assuming that the $a_{\ell m}$ are Gaussian-distributed, the information about the large-scale structure is encoded in the covariance of the $a_{\ell m}$, i.e., the angular power spectra C_{ℓ}^{AB} :

$$\langle a_{\ell m}^{W_A}(z_1) a_{\ell' m'}^{*W_B}(z_2) \rangle = \delta_{\ell\ell'} \delta_{mm'} C_{\ell}^{AB}(z_1, z_2). \quad (2)$$

We can write the angular power as (Challinor & Lewis 2011)

$$C_{\ell}^{AB}(z_i, z_j) = 4\pi \int d \ln k \Delta_{\ell}^{W_A}(z_i, k) \Delta_{\ell}^{W_B}(z_j, k) \mathcal{P}(k), \quad (3)$$

where

$$\mathcal{P}(k) = A_s \left(\frac{k}{k_0} \right)^{n_s-1}, \quad (4)$$

is the primordial power spectrum of the curvature perturbation. The pivot scale is $k_0 = 0.05 \text{ Mpc}^{-1}$, A_s is the amplitude and n_s is the spectral index. The $\Delta_{\ell}^{W_A}(z_i, k)$ are the observed transfer functions at comoving scale k , which include the observational effects from the window function W_A and redshift distribution of sources p^A :

$$\Delta_{\ell}^{W_A}(z_i, k) = \int dz p^A(z) W_A(z_i, z) \Delta_{\ell}^A(z, k). \quad (5)$$

Here $\Delta_{\ell}^A(z, k)$ is the theoretical transfer function. If we were able to measure infinitesimal shells in redshift then our window function would just be a Dirac delta function and the observed and theoretical transfer functions would be the same. The product $p^A W_A$ is in effect a probability distribution function for a source to contribute to the signal in the bin, and is thus normalised to unity: $\int dz p^A(z) W_A(z_i, z) = 1$ for all z_i .

The full expression (including all GR corrections) for the theoretical transfer function of a map of intensity is (Hall et al. 2013)

$$\begin{aligned} \Delta_{\ell}^A &= \Delta_{\ell}^{\text{standard}} + \Delta_{\ell}^{\text{Doppler}} + \Delta_{\ell}^{\text{SW}} + \Delta_{\ell}^{\text{ISW}}, \\ \Delta_{\ell}^{\text{standard}} &= b^A \delta_k^s j_{\ell}(k\chi) + \frac{k}{\mathcal{H}} v_k j_{\ell}'(k\chi), \\ \Delta_{\ell}^{\text{Doppler}} &= \left(2 - b_e^A + \frac{\dot{\mathcal{H}}}{\mathcal{H}^2} \right) v_k j_{\ell}'(k\chi), \\ \Delta_{\ell}^{\text{SW}} &= \left[(b_e^A - 3) \frac{\mathcal{H}}{k} v_k + \left(3 - b_e^A + \frac{\dot{\mathcal{H}}}{\mathcal{H}^2} \right) \psi_k + \frac{\dot{\phi}_k}{\mathcal{H}} \right] j_{\ell}(k\chi), \\ \Delta_{\ell}^{\text{ISW}} &= \left(2 - b_e^A + \frac{\dot{\mathcal{H}}}{\mathcal{H}^2} \right) \int_0^{\chi} d\tilde{\chi} (\dot{\phi}_k + \dot{\psi}_k) j_{\ell}(k\tilde{\chi}). \end{aligned} \quad (6)$$

To simplify notation we suppressed the redshift and k dependence (except in the spherical Bessel functions). Here $\mathcal{H} = \dot{a}/a$ is the conformal Hubble parameter and χ is the comoving line-of-sight distance. Equation (6) is in Newtonian gauge, but the comoving-synchronous density contrast δ_k^s arises from the relativistic definition of clustering bias (Challinor & Lewis 2011; Bonvin & Durrer 2011; Bruni et al. 2012; Jeong et al. 2012). The other perturbations are the peculiar velocity v_k (where ikv_k is the velocity divergence), and the metric perturbations, defined by

$$ds^2 = a^2 \left[- (1 + 2\psi) dt^2 + (1 - 2\phi) dx^2 \right]. \quad (7)$$

¹ Note that the GR lensing contribution to number counts can be significant on sub-equality scales.

² www.skatelescope.org

³ http://spherex.caltech.edu

The evolution bias $b_e^A(z)$ accounts for redshift evolution of the sources:

$$b_e^A = -\frac{\partial \ln n^A}{\partial \ln(1+z)}, \quad (8)$$

where n^A is the comoving number density of A-sources.

The second line of (6) contains the standard density + Kaiser redshift-space distortions (RSD) terms. The third line is the Doppler term.

The fourth line is the SW contribution from the metric potentials ϕ, ψ . We have included in this contribution the relativistic correction to clustering bias, which is the first term in the square brackets, since the velocity potential v_k/k can be rewritten in terms of ϕ, ψ as follows. Using the Poisson equation, $-k^2\phi_k = 3\Omega_m\mathcal{H}^2\delta_k^s/2$, and the continuity equation,

$$ikv_k = f\mathcal{H}\delta_k^s, \quad f = -\frac{d \ln D}{d \ln(1+z)}, \quad (9)$$

where f is the growth rate, we find that

$$\frac{\mathcal{H}}{k}v_k = -i\frac{2f}{3\Omega_m}\phi_k. \quad (10)$$

The $\dot{\phi}_k$ term in the SW contribution can be rewritten as

$$\frac{\dot{\phi}_k}{\mathcal{H}} = f\phi_k - \psi_k, \quad (11)$$

using the momentum constraint, $\dot{\phi}_k + \mathcal{H}\psi_k = (3i\Omega_m\mathcal{H}^2/2)v_k/k$.

The last line of (6) is the ISW effect in the observed clustering. The last three lines together are the GR corrections, which are only relevant on ultra-large scales. Furthermore the ISW term is only important in the presence of dark energy, i.e., at low redshift.

In the concordance model $\psi = \phi$ and $\mathcal{H}/\mathcal{H}^2 = 1 - 3\Omega_m/2$, so that we can rewrite the GR parts as

$$\Delta_\ell^{\text{Doppler}} = \left(3 - \frac{3}{2}\Omega_m - b_e^A\right)v_k j_\ell'(k\chi), \quad (12)$$

$$\Delta_\ell^{\text{A SW}} = \left[(3 - b_e^A)\left(1 + i\frac{2f}{3\Omega_m}\right) + f - \frac{3}{2}\Omega_m\right]\phi_k j_\ell(k\chi)\chi(13)$$

$$\Delta_\ell^{\text{ISW}} = (6 - 3\Omega_m - 2b_e^A)\int_0^\chi d\tilde{\chi}\dot{\phi}_k j_\ell(k\tilde{\chi}). \quad (14)$$

Local primordial non-Gaussianity alters the clustering bias on ultra-large scales (Dalal et al. 2008; Matarrese & Verde 2008):

$$b^A(z, k) = b_G^A(z) + D(z_{\text{dec}})(1 + z_{\text{dec}})f_{\text{NL}}\frac{3[b_G^A(z) - 1]\delta_c\Omega_{m0}H_0^2}{D(z)T(k)k^2}, \quad (15)$$

where b_G is the linear Gaussian bias, $\delta_c \approx 1.69$ is the critical matter density contrast for spherical collapse, T is the matter transfer function (normalised to 1 on large scales) and D is the growth factor (normalised to 1 at $z = 0$). The factor $D(z_{\text{dec}})(1 + z_{\text{dec}}) \approx 1.27$ ensures that we use the CMB definition of f_{NL} .

On ultra-large scales $T(k) \approx 1$, and the bias is dominated by the f_{NL} correction with a k^{-2} dependence. The same k -dependence holds for the SW terms in (6). On the other hand, the Doppler term has a k^{-1} dependence from (9). We therefore expect degeneracies between f_{NL} and the potential terms, but f_{NL} and the Doppler term should be fairly independent.

3 SURVEYS

There are 3 intrinsic tracer quantities that we need to determine: the clustering bias, the evolution bias and the redshift distribution

of sources. In addition, we need to specify the instrumental noise. We will neglect shot-noise of the lines, which is a safe assumption for H α (Gong et al. 2011) and H α (Fonseca et al. 2017b). The angular power spectrum of instrumental noise for IM experiments is similar to that of CMB experiments (Knox 1995). It is given by $\mathcal{N}_\ell = \sigma^2 \Omega_{\text{pixel}}$, where σ is the sensitivity of the experiment for a chosen survey strategy and Ω_{pixel} is the pixel area given by the experiment's angular resolution. Note that the noise angular power does not depend on the angular scale ℓ . Following the approach of Knox (1995), beam effects should be included in the signal, not in the noise. While the two approaches are equivalent for a single tracer in a single redshift bin, this does not hold for multiple tracers or multiple redshift bins. The effect of the beam is to reduce power at high ℓ . For the purposes of this paper, we neglect beam effects, which is reasonable since we are only interested in the largest cosmological scales. The noise between frequency bins i and j should be uncorrelated, so that the general expression for the instrumental noise angular power spectrum is given by

$$\mathcal{N}_{\ell,ij} = \sigma_i^2 \Omega_{\text{pixel},i} \delta_{ij}. \quad (16)$$

3.1 H α IM with an SKA1-like survey

The redshift distribution of sources is given by the average H α temperature, $p^{\text{H}\alpha}(z) \propto T^{\text{H}\alpha}(z)$. (For a detailed discussion on separating $T^{\text{H}\alpha}(z)$ from H α bias and other cosmological parameters in the measured power spectrum, see Bull et al. (2015).) We follow Santos et al. (2015) to compute both the Gaussian bias $b_G^{\text{H}\alpha}(z)$ (their Eq. 2.5) and temperature (their Eq. 2.1). Figure 1 shows the H α Gaussian bias as a function of redshift (thin solid blue). We can write the comoving number density of H α atoms in terms of the temperature: $n^{\text{H}\alpha}(z) \propto T^{\text{H}\alpha}(z)H(z)/(1+z)^2$. Then the evolution bias (8) becomes

$$b_e^{\text{H}\alpha}(z) = -\frac{\partial \ln [T^{\text{H}\alpha}(z)H(z)]}{\partial \ln(1+z)} - 2. \quad (17)$$

The experimental noise angular power spectrum in a redshift bin i for an H α IM experiment in single-dish mode is given by

$$\mathcal{N}_{ij}^{\text{H}\alpha} = \frac{4\pi f_{\text{sky}} T_{\text{sys},i}^2}{2N_d t_{\text{tot}} \Delta v_i^{\text{H}\alpha}} \delta_{ij}, \quad (18)$$

where $T_{\text{sys},i}$ is the system temperature for bin i , $\Delta v_i^{\text{H}\alpha}$ is the frequency width of the bin for H α , N_d the number of collecting dishes, t_{tot} the total observation time and f_{sky} the observed fraction of the sky (we take $f_{\text{sky}} = 0.75$). Note that (18) follows from (16), since

$$\sigma_i^{\text{H}\alpha} = \frac{T_{\text{sys},i}}{(2N_d \Delta v_i^{\text{H}\alpha} t_{\text{pixel},i})^{1/2}}, \quad (19)$$

$$\Omega_{\text{pixel},i}^{\text{SKA}} = \frac{\Omega_{\text{survey}}}{N_{\text{pixel},i}} = \frac{4\pi f_{\text{sky}}}{t_{\text{tot}}/t_{\text{pixel},i}}, \quad (20)$$

where $t_{\text{pixel},i}$ is the integration time per pixel at frequency bin i , $N_{\text{pixel},i}$ is the number of pixels in slice i and Ω_{survey} is the total surveyed area. We take $T_{\text{sys}} = T_{\text{rec}} + T_{\text{sky}}$, where the receiver temperature is $T_{\text{rec}} = 25$ K and the sky contribution is given by $T_{\text{sky}} = 60 \times (300 \text{ MHz}/\nu)^{2.55}$ K (see caption of Table 2 in Santos et al. 2015). We also assumed that $N_d t_{\text{tot}} = 2 \times 10^6$ hr.

3.2 H α IM with a SPHEREx-like survey

The most energetic line of the Balmer series, H α , with a rest-frame wavelength of 656 nm, is also one of the strongest emission lines from galaxies. The emission comes from recombination of hydrogen atoms that have been ionised by young UV emitting stars. The

H α line is therefore a tracer of star-forming galaxies (Laureijs et al. 2011; Amendola et al. 2013; Spergel et al. 2015). The linear Gaussian bias $b_G^{\text{H}\alpha}(z)$ for H α IM is given by Fonseca et al. (2017b) and shown in Fig. 1 (thick solid red line). The H α bias is consistent with the measurement $b_G^{\text{H}\alpha} = 2.4^{+0.1}_{-0.2}$ at $z = 2.23$ of Geach et al. (2012).

The average line intensity computed in Fonseca et al. (2017b) is well described by the fit

$$I_v^{\text{H}\alpha}(z) = \frac{7.79 \times 10^{-15} (1+z)^{1.17}}{1 + 1.37 \times 10^{-3} (1+z)^{6.61}} \text{ erg/s/cm}^2/\text{Hz/Sr}. \quad (21)$$

For H α IM the redshift distribution of sources is given by the intensity, i.e., $p^{\text{H}\alpha}(z) \propto I_v^{\text{H}\alpha}(z)$. We assume that $b_e^{\text{H}\alpha}(z) \simeq b_e^{\text{H}\text{I}}(z)$, since the comoving number density of hydrogen atoms is independent of hydrogen emission lines. This follows from assuming that the number density of H α emitters is a constant fraction (or with a negligible redshift evolution) of the average number of neutral hydrogen atoms.

The proposed space telescope SPHEREx would have a spectral resolution of $\lambda/\Delta\lambda = 41.5$ for $0.75 < \lambda < 4.1 \mu\text{m}$. Although it is mainly intended as a galaxy survey, it can have a H α IM mode. The proposed instrument has a pixel size $\Omega_{\text{pixel}}^{\text{SPHEREx}} = 6.2'' \times 6.2'' \sim 10^{-9}$ sr. We assume a constant 1σ flux sensitivity of $\sigma_F \sim 10^{-17}$ erg/s/cm 2 , higher than the SPHEREx 5σ sensitivity of 18.4 AB magnitudes (Doré et al. 2014). According to Silva et al. (2017) (their Fig. 1), (21) may under-estimate the average H α intensity. The results are sensitive to the ratio $I_v^{\text{H}\alpha}/\sigma(I_v^{\text{H}\alpha})$ and not to the sensitivity or the intensity alone. For this reason, we choose to increase flux sensitivity instead of increasing the intensity of the signal. The flux sensitivity translates to an uncertainty in the intensity given by $\sigma(I_v^{\text{H}\alpha}) = \sigma_F / (\Omega_{\text{pixel}}^{\text{SPHEREx}} \delta\nu)$, for the experimental angular resolution $\Omega_{\text{pixel}}^{\text{SPHEREx}}$ and the experimental frequency resolution $\delta\nu$ at observed frequency ν . We use survey strategies with thicker frequency bins than the resolution one. This reduces the error in determining the intensity by $\sigma_i(I_v^{\text{H}\alpha}) = \sigma(I_v^{\text{H}\alpha}) (N_{v,i})^{-1/2}$, where the number of resolution bins in a survey bin is $N_{v,i} = \Delta\nu_i^{\text{H}\alpha}/\delta\nu$. Note that $\Delta\nu_i^{\text{H}\alpha}$ is the frequency width of the bin for H α . The noise angular power spectrum is then given by (16) as

$$\begin{aligned} N_{ij}^{\text{H}\alpha} &= \left[\sigma_i(I_v^{\text{H}\alpha}) \right]^2 \Omega_{\text{pixel}}^{\text{SPHEREx}} \delta_{ij}, \\ &= \left(\frac{\sigma_F}{\Omega_{\text{pixel}}^{\text{SPHEREx}} \delta\nu_i} \right)^2 \frac{\delta\nu_i}{\Delta\nu_i^{\text{H}\alpha}} \Omega_{\text{pixel}}^{\text{SPHEREx}} \delta_{ij}, \end{aligned} \quad (22)$$

where $\delta\nu_i$ is the frequency resolution of SPHEREx at the central frequency of bin i .

4 FISHER FORECAST ANALYSIS

The Fisher matrix for a set of parameters ϑ_i is

$$F_{\vartheta_i, \vartheta_j} = \frac{1}{2} \text{Tr} \left[(\partial_{\vartheta_i} C) \Gamma^{-1} (\partial_{\vartheta_j} C) \Gamma^{-1} \right], \quad \Gamma = C + \mathcal{N}, \quad (23)$$

where C is the covariance matrix of the estimator and \mathcal{N} is the noise term. For IM, shot-noise is subdominant to instrumental noise, so we can safely assume that the noise term is independent of the ϑ_i . Since the observables are the $\alpha_{\ell m}^{AB}$, the estimator's covariance is the angular power spectrum $C_{\ell}^{AB}(z_i, z_j)$. Considering the information in a given range of multipoles, we rewrite (23) as (Tegmark et al. 1997)

$$F_{\vartheta_i, \vartheta_j} = \sum_{\ell_{\min}}^{\ell_{\max}} \frac{(2\ell+1)}{2} f_{\text{sky}} \text{Tr} \left[(\partial_{\vartheta_i} C_{\ell}) \Gamma_{\ell}^{-1} (\partial_{\vartheta_j} C_{\ell}) \Gamma_{\ell}^{-1} \right]. \quad (24)$$

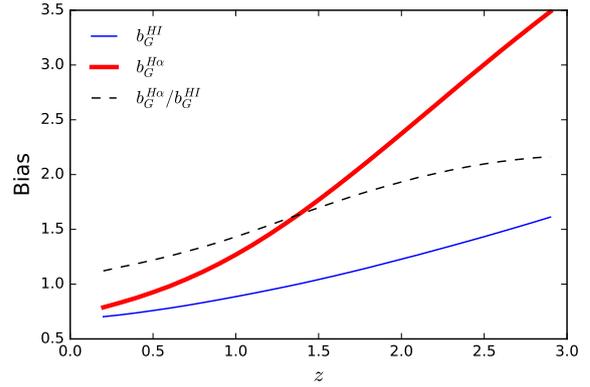

Figure 1. Gaussian bias of H I (Santos et al. 2015, thin solid blue) and H α (Fonseca et al. 2017b, thick solid red) emission lines. The ratio of the biases is also shown (dashed).

The sky fraction f_{sky} enters via an approximation that accounts for the fact that not all m are accessible at a given ℓ . For the MT technique one requires that the sky maps of the differently biased tracers cover the same sky area and have the same redshift slicing. Then the covariance matrix is (Ferramacho et al. 2014)

$$C_{\ell}^{AB}(z_i, z_j) = \begin{pmatrix} C_{\ell,ij}^{\text{H}\text{I},\text{H}\text{I}} & C_{\ell,ij}^{\text{H}\text{I},\text{H}\alpha} \\ C_{\ell,ij}^{\text{H}\alpha,\text{H}\text{I}} & C_{\ell,ij}^{\text{H}\alpha,\text{H}\alpha} \end{pmatrix}, \quad (25)$$

where i, j indicate the redshift bins. Assuming that we are dealing with Gaussian likelihoods, the inverse of the Fisher matrix is a good approximation to the parameter covariance. In this case the forecast marginal error for parameter ϑ_i is

$$\sigma_{\vartheta_i} = [(F^{-1})_{\vartheta_i, \vartheta_i}]^{1/2}. \quad (26)$$

We consider the set of parameters

$$\vartheta_{\alpha} = \left\{ \ln A_s, \ln n_s, \ln \Omega_{\text{cdm}}, \ln \Omega_b, w, \ln H_0, b_G^{\text{H}\text{I}}(z_i), b_G^{\text{H}\alpha}(z_i), f_{\text{NL}}, \varepsilon_{\text{Doppler}}, \varepsilon_{\text{SW}}, \varepsilon_{\text{ISW}} \right\}. \quad (27)$$

For the cosmological parameters we used the fiducial values: $A_s = 2.142 \times 10^{-9}$, $n_s = 0.967$, $\Omega_{\text{cdm}} = 0.26$, $\Omega_b = 0.05$, $w = -1$, $H_0 = 67.74$ km/s/Mpc and $f_{\text{NL}} = 0$. The fiducial values for the Gaussian clustering biases were discussed in §3 and are shown in Fig. 1. The parameters $\varepsilon_{\text{Doppler}}$, ε_{SW} and ε_{ISW} are introduced to assess how well we can measure each individual contribution of the GR effects (12)–(14). They have a fiducial value of $\varepsilon = 1$, and are intrinsically defined by

$$\Delta_{\ell}^A = \Delta_{\ell}^{\text{standard}} + \varepsilon_{\text{Doppler}} \Delta_{\ell}^{\text{Doppler}} + \varepsilon_{\text{SW}} \Delta_{\ell}^{\text{SW}} + \varepsilon_{\text{ISW}} \Delta_{\ell}^{\text{ISW}}. \quad (28)$$

To compute the angular power spectra and their derivatives with respect to the cosmological parameters we used a modified version⁴ of CAMB_sources. The derivatives with respect to $\ln \Omega_{\text{cdm}}$, $\ln \Omega_b$, w , $\ln H_0$ are evaluated numerically using the 5-point stencil method. For the remaining parameters, they are done analytically (see Appendix A). The supporting Python wrappers to compute the derivatives and the Jupyter Notebook used to compute the Fisher matrix and results presented in this paper can be found in the GitHub repository⁵.

Table 1. Marginal errors on f_{NL} , $\varepsilon_{\text{Doppler}}$, ε_{SW} and ε_{ISW} for different binings Δz , for the two IM surveys separately and combined via MT analysis, assuming $f_{\text{sky}} = 0.75$, $0.2 \leq z \leq 3$, and the instrumental noise given in §3.

Δz		$\sigma(f_{\text{NL}})$	$\sigma(\varepsilon_{\text{Doppler}})$	$\sigma(\varepsilon_{\text{SW}})$	$\sigma(\varepsilon_{\text{ISW}})$
0.2	H α	5.0	5.9	14	11
	H α	3.9	8.1	30	22
	MT	1.2	0.64	6.0	9.7
0.1	H α	4.3	4.9	12	11
	H α	3.5	6.8	27	22
	MT	1.1	0.39	5.6	9.5
Δz_{min}	H α	3.5	4.3	11	9.5
	H α	3.4	6.3	26	20
	MT	1.0	0.33	4.9	8.3

Table 2. As in Table 1, for conditional errors on f_{NL} .

Δz	H α	H α	MT
0.2	2.4	1.4	1.0
0.1	2.1	1.3	0.92
Δz_{min}	1.8	1.3	0.86

We assume a redshift range $0.2 \leq z \leq 3$ and we compare three binning strategies to see their effects on forecasts: conservative, with 14 thick bins of width $\Delta z = 0.2$; less conservative, with 28 bins of size $\Delta z = 0.1$; using the full spectral resolution of SPHEREx, i.e., $\Delta z_{\text{min}} = (1+z)/41.5$. SKA1 has much higher redshift resolution, but the MT requires equal binning.

The Fisher matrix depends on the surveyed area either directly via $f_{\text{sky}} = \Omega_{\text{survey}}/4\pi$ in (24), or indirectly via the maximum accessible scale, $\ell_{\text{min}} = 1 + \text{integer}(\pi/\sqrt{\Omega_{\text{survey}}})$. We assume an overlap sky fraction of $f_{\text{sky}} = 0.75$, so that $\ell_{\text{min}} = 2$.

Our focus is on ultra-large scale effects, so we do not need to model nonlinear scales, $k > k_{\text{NL}}$, where (Smith et al. 2003)

$$k_{\text{NL}}(z) \approx k_{\text{NL},0} (1+z)^{2/(2+n_s)}, \quad k_{\text{NL},0} \approx 0.2h \text{ Mpc}^{-1}, \quad (29)$$

$$\ell_{\text{NL}} \approx \chi k_{\text{NL}}, \quad (30)$$

and we used the Limber approximation. We cap contributions to the Fisher matrix from a redshift bin i at $\ell_{\text{max}}^i = \max(300, \ell_{\text{NL}}^i)$. This is only relevant for the lowest redshift bins where ℓ_{NL} is small. At high z , $\ell_{\text{max}} = 300$ is conservative, but this has a negligible effect on our results.

5 RESULTS

The forecast marginal errors for the ultra-large scale parameters f_{NL} , $\varepsilon_{\text{Doppler}}$, ε_{SW} and ε_{ISW} are summarised in Table 1. Results are shown for each binning strategy. For comparison, the single-tracer constraints with the same binning are shown. Increasing the redshift resolution does improve the results mildly. (Note that the f_{NL} constraints for SKA1 would improve considerably if the greater available spectral resolution were used.) As expected, the MT technique improves the errors, especially for the Doppler term. The forecast $\sim 3\sigma$ detection of the Doppler term is consistent with the results of Abramo & Bertacca (2017), who applied the MT technique to two galaxy surveys, based on the monopole and dipole of the Cartesian power spectrum. We marginalised over all the other parameters, since our focus is on f_{NL} and the GR effects. Marginalisation includes any correlations between A_s and the ε parameters in the quoted errors. Since A_s is an overall scale-independent amplitude, while f_{NL} and the ε parameters are multiplied by terms with $1/k$ or $1/k^2$ dependences, we expect little correlation with A_s .

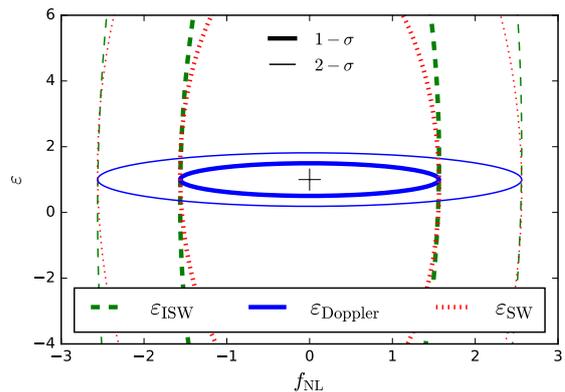

Figure 2. The 1σ (thick) and 2σ (thin) contours for the marginal errors of f_{NL} and the Doppler (solid blue), SW (dashed red) and ISW (dot-dashed green) GR effects. ($f_{\text{sky}} = 0.75$, $0.2 \leq z \leq 3$ and redshift resolution Δz_{min} .)

In Table 2, for comparison we give the conditional errors on f_{NL} . For the single-tracer case there is a substantial improvement from marginal to conditional error, as expected. This is not true for the multi-tracer case: the auto- and cross-correlations reduce degeneracies between parameters, leading to a smaller improvement. The single-tracer case does not give prospects of crossing the $\sigma_{f_{\text{NL}}} \sim 1$ threshold, due to cosmic variance, in agreement with previous results (Camera et al. 2013; Camera et al. 2015c; Alonso et al. 2015a; Raccanelli et al. 2016). The MT results just reach $\sigma_{f_{\text{NL}}} \approx 1$ (marginal error), not as good as MT with H α IM and photometric surveys (Alonso & Ferreira 2015; Fonseca et al. 2015). The MT technique is known to improve with the increasing difference in bias-like parameters of the tracers. For two IM surveys, the clustering biases have a small ratio (see Fig. 1), the evolution biases are equal, and both have no magnification bias. By contrast, an IM and a photo- z survey have significant differences in all 3 astrophysical parameters (Alonso & Ferreira 2015; Fonseca et al. 2015).

Constraints on f_{NL} are intimately connected to those on the GR effects, given the partial degeneracy between the effects of primordial non-Gaussianity and those of GR corrections (Bruni et al. 2012; Jeong et al. 2012; Camera et al. 2015). This can be seen in Fig. 2, showing the forecast 1σ and 2σ marginalised contours for f_{NL} with the different GR effects. Table 1 shows that the Doppler term is well constrained by the IM MT (with maximal redshift resolution), implying that it would be detectable at $\sim 3\sigma$. Neither the SW nor the ISW terms are constrained by the MT.

With the MT we are no longer cosmic variance limited. The instrumental noise is thus the most important source of uncertainty for ultra-large scale parameters. We see this in Figs. 3 and 4, showing the forecast errors as a function of the fraction of the reference noise ($= 1$), for the three different binning strategies. While the errors are sensitive to the redshift resolution, they are even more sensitive to the experimental noise. The reference noise is given in §3 and we vary the noise simultaneously for the two experiments, allowing also for higher noise. While for SKA1 one can lower the noise by increasing the observation time, one would need to wait for a more futuristic H α experiment to improve sensitivity.

It is also interesting to compare how this combination of tracers would perform if we bundle all GR effects together, as in Alonso & Ferreira (2015) and Fonseca et al. (2015). The forecast result using the MT technique ranges from $\sigma_{\varepsilon_{\text{GR}}}(\delta z = 0.2) = 0.63$

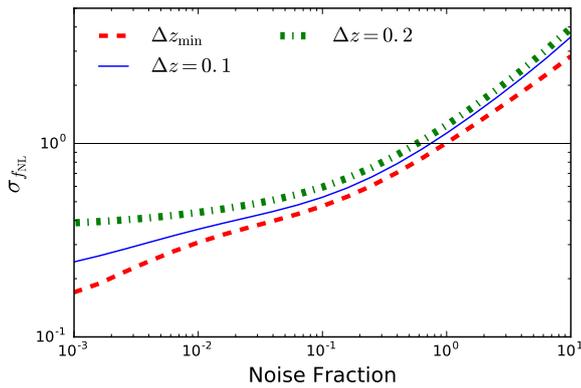

Figure 3. Dependence of the forecast $\sigma(f_{\text{NL}})$ on the noise, as a fraction of the reference noise ($= 1$), for the three binnings: $\Delta z = 0.2$ (thick green dot-dashed), $= 0.1$ (thin blue solid), $= \Delta z_{\text{min}}$ (red dashed). The horizontal line indicates the threshold $\sigma(f_{\text{NL}}) = 1$. ($f_{\text{sky}} = 0.75$, $0.2 \leq z \leq 3$.)

to $\sigma_{\varepsilon_{\text{GR}}}(\delta z_{\text{min}}) = 0.33$. This is consistent with Table 1, i.e. detection of the collective GR effects is basically detection of the Doppler effect for the MT of the two intensity maps.

6 DISCUSSION

We have shown that a MT combination of intensity maps of two hydrogen lines can detect the GR Doppler contribution to intensity, but the remaining GR effects, SW and integrated SW, are not detectable. In the best case scenario, the Doppler term is constrained at 3σ . To our knowledge, this is the first time that the GR effects have been separately constrained. (The GR effect of weak lensing convergence has been separately constrained, but this effect vanishes at first order for intensity mapping.)

By Eqs. (12)–(14), the Doppler term scales as $v_k \propto \mathcal{H}/k$, while the SW and ISW terms scale as $\phi_k \propto \mathcal{H}^2/k^2$. The Doppler effect is thus stronger for $k > \mathcal{H}$, and is the dominant GR contribution to the auto-correlations of each intensity map. This is illustrated in Fig. 5. For cross-bin correlations, we expect that the ISW should dominate for widely separated bins. This is confirmed by Fig. 6, which shows that the angular power cross-spectrum between bins at $z = 0.5$ and $z = 2.5$ is dominated by the low- z density correlation with high- z ISW.

We also showed that the same MT combination can constrain the primordial non-Gaussianity parameter down to the level $\sigma(f_{\text{NL}}) \sim 1$. In contrast to other works where the MT has been used to break through the $\sigma_{f_{\text{NL}}} \sim 1$ threshold (see eg Ferramacho et al. 2014; Yamauchi et al. 2014; Doré et al. 2014; Alonso & Ferreira 2015; Fonseca et al. 2015), we used two intensity maps rather than combinations of galaxy surveys or a galaxy survey with H I IM. The combination of maps of intensity of two hydrogen lines is not optimal to measure the local non-Gaussian parameter f_{NL} , since the clustering biases are both close to one.

We can explain the difference in detectability amongst the GR terms as follows. The observed fluctuations satisfy

$$\Delta^{\text{H}\alpha} - \Delta^{\text{H}\text{I}} = (b^{\text{H}\alpha} - b^{\text{H}\text{I}})\delta^s, \quad (31)$$

since the evolution biases are equal, $b_e^{\text{H}\text{I}} = b_e^{\text{H}\alpha}$. From this we can

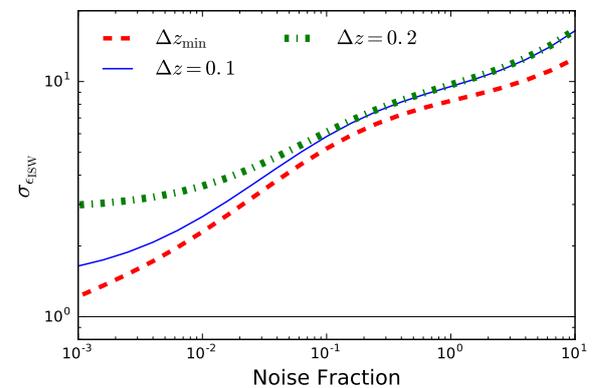

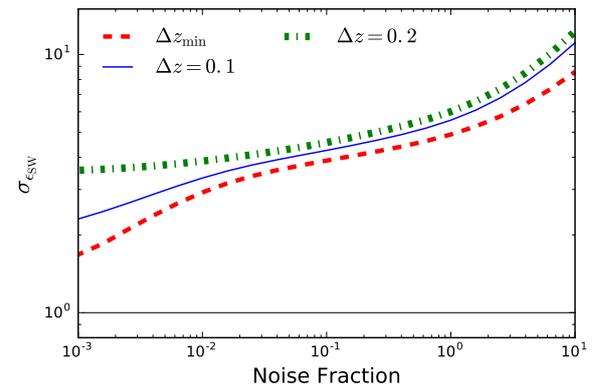

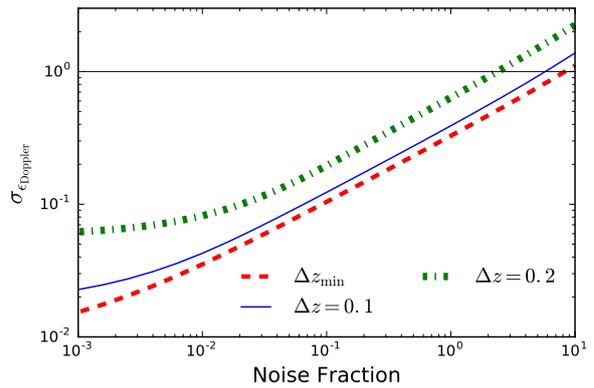

Figure 4. As in Fig. 3, for the GR parameters: $\varepsilon_{\text{Doppler}}$ (top), ε_{SW} (middle), ε_{ISW} (bottom).

find a combination that excludes the density constraint:

$$\Delta^{\text{H}\alpha} - \frac{b^{\text{H}\alpha}}{b^{\text{H}\text{I}}}\Delta^{\text{H}\text{I}} = \left(1 - \frac{b^{\text{H}\alpha}}{b^{\text{H}\text{I}}}\right) \left[\Delta^{\text{RSD}} + \Delta^{\text{Doppler}} + \Delta^{\text{SW}} + \Delta^{\text{ISW}} \right]. \quad (32)$$

While the difference of the fluctuations is only sensitive to the clustering bias (and thus primordial non-Gaussianity), the second combination is mainly sensitive to velocity terms – RSD and Doppler. The RSD contribution is the dominant term, but the Doppler contribution correlates perfectly with RSD, thus enhancing the chances of detecting this GR term. By the same token, the fact that we still have RSD in the second combination makes it the dominant source of intrinsic uncertainty if we want to measure the SW and ISW in the large-scale structure. The second combination therefore illustrates why the Doppler term is detectable while the SW and ISW

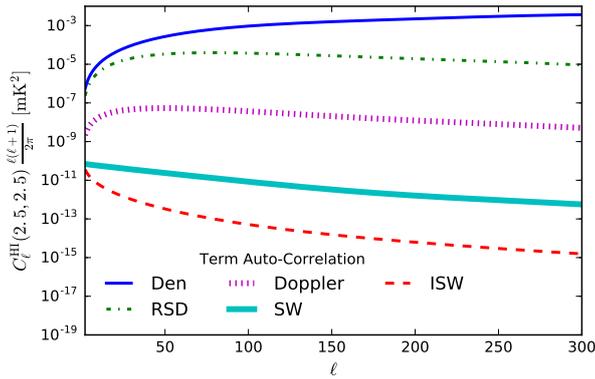

Figure 5. Angular power auto-spectra $C_\ell(2.5, 2.5)$ at $z = 2.5$ of each term in Eq. (6): density (thin solid blue); RSD (thin dot-dashed green); Doppler (thick dotted magenta); SW (thick solid cyan); ISW (thin dashed red). We use a Gaussian window function with $\sigma_z = 0.05$.

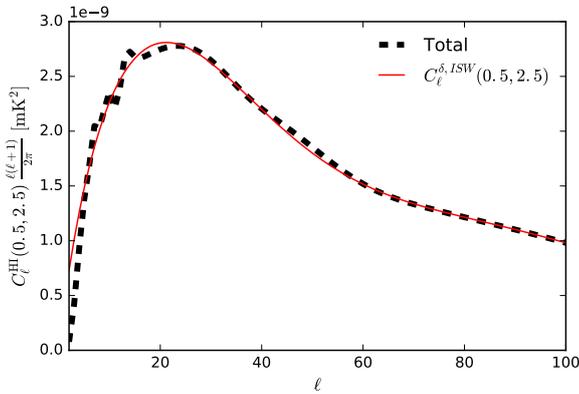

Figure 6. Angular power cross-spectra $C_\ell(0.5, 2.5)$: total spectrum (dashed black); density ($z = 0.5$)–ISW ($z = 2.5$) (solid red).

terms are not. The latter terms are overwhelmed by the uncertainty in RSD. If we neglected RSD and Doppler effects, i.e. if we assumed that density and SW/ ISW were the only contributions, then the second combination of fluctuations implies that SW and ISW should be detectable.

We have assumed that the foregrounds for the two intensity maps have been dealt with using well-developed cleaning techniques (see, e.g. Wolz et al. 2015; Silva et al. 2017, for H α and H α , respectively). Note that any foreground residuals left after the cleaning/masking procedure will mainly affect $C_\ell^{\text{H}\alpha, \text{H}\alpha}$ and $C_\ell^{\text{H}\alpha, \text{H}\alpha}$, since in $C_\ell^{\text{H}\alpha, \text{H}\alpha}$ the foregrounds of H α should not correlate with those of H α . In practice, such foreground removals will affect the minimum multipole ℓ_{\min} that we can use to compute parameter constraints. In Fig. 7 we plot the dependence of $\sigma(f_{\text{NL}})$ and $\sigma(\varepsilon_{\text{Doppler}})$ as a function of ℓ_{\min} . While the constraints on the Doppler term are not appreciably sensitive to ℓ_{\min} , the error on f_{NL} degrades more quickly as one discards the largest scales. Alonso et al. (2015b) showed that H α foreground removal mainly affects the largest modes in the line-of-sight (their Fig. 3 right panel). Despite this, the angular power spectrum can still be recovered on large scales (low ℓ) but with a larger uncertainty (their Fig. 3 left panel).

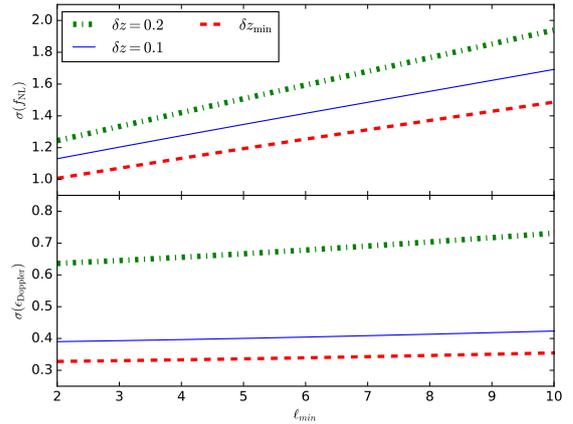

Figure 7. Forecast errors in measuring f_{NL} (top) and the Doppler term (bottom) as a function of the largest included scale ℓ_{\min} , for the three chosen binning strategies.

A more realistic approach should take these larger uncertainties at low ℓ into account, although it is beyond the scope of this paper.

APPENDIX A: ANALYTICAL DERIVATIVES OF PARAMETERS

To improve on numerics we take analytical derivatives whenever possible. Otherwise we computed the numerical derivatives using the 5-point stencil expression,

$$\frac{dC_\ell}{d\theta} \simeq \frac{C_\ell(\theta - 2h) - 8C_\ell(\theta - h) + 8C_\ell(\theta + h) - C_\ell(\theta + 2h)}{12h}, \quad (\text{A1})$$

for a given interval h . This is done for $\ln \Omega_{\text{cdm}}$, $\ln \Omega_b$, w , $\ln H_0$.

For the parameters of the primordial power spectra:

$$\frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial A_s} = \frac{C_\ell^{AB}(z_i, z_j)}{A_s} \quad (\text{A2})$$

$$\frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial n_s} = 4\pi \int d \ln k \Delta_\ell^{WA}(z_i, k) \Delta_\ell^{WB}(z_j, k) \ln\left(\frac{k}{k_0}\right) \mathcal{P}(k). \quad (\text{A3})$$

The derivatives with respect to the (Gaussian) clustering bias in each bin are

$$\begin{aligned} \frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial b_G^C(z_n)} = & \int d \ln k \left[\Delta_\ell^{WB}(z_j) \delta_{ni} \delta^{AC} \int dz' p^A(z') W(z', z_i) \delta_{kj\ell}(k\chi) \right. \\ & \left. + \Delta_\ell^{WA}(z_i) \delta_{nj} \delta^{BC} \int dz'' p^B(z'') W(z'', z_j) \delta_{kj\ell}(k\chi) \right] \mathcal{P}(k). \end{aligned} \quad (\text{A4})$$

Note that this is different than just asking for density in one window and making $b_n = 1$, since the code is in Newtonian gauge. We change the code to compute each term in the last line.

The derivative with respect to f_{NL} is

$$\begin{aligned} \frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial f_{\text{NL}}} = & \int d \ln k \left[\Delta_\ell^{WB}(z_j) \int dz' p^A(z') W(z', z_i) \frac{\partial \Delta b_i}{\partial f_{\text{NL}}} \delta_{kj\ell}(k\chi) \right. \\ & \left. + \Delta_\ell^{WA}(z_i) \int dz'' p^B(z'') W(z'', z_j) \frac{\partial \Delta b_j}{\partial f_{\text{NL}}} \delta_{kj\ell}(k\chi) \right] \mathcal{P}(k) \\ = & C_\ell^{AB}(z_i^{\delta f_{\text{NL}}}, z_j^{\text{all}}) + C_\ell^{AB}(z_i^{\text{all}}, z_j^{\delta f_{\text{NL}}}), \end{aligned} \quad (\text{A5})$$

with

$$\frac{\partial \Delta b_i}{\partial f_{\text{NL}}} = 3[b_G(z) - 1] D(z_{\text{dec}}) (1 + z_{\text{dec}}) \frac{\Omega_m H_0^2 \delta_c}{D(z) T(k) k^2} = \frac{\Delta b_i}{f_{\text{NL}}}. \quad (\text{A6})$$

To identify if a GR correction to the angular power can be detected, we introduced the fudge factors in (28), which we can rewrite as

$$\Delta_\ell^A = \Delta_\ell^{A \text{ other}} + \varepsilon_{\text{term}} \Delta_\ell^{A \text{ term}}. \quad (\text{A7})$$

One can then derive the expression

$$\begin{aligned} \frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial \varepsilon_{\text{term}}} = & \int d \ln k \left[\Delta_\ell^{WA \text{ term}}(z_i) \Delta_\ell^{WB}(z_j) \right. \\ & \left. + \Delta_\ell^{WA}(z_i) \Delta_\ell^{WB \text{ term}}(z_j) \right] \mathcal{P}(k). \end{aligned} \quad (\text{A8})$$

The strategy is the same as for the biases and f_{NL} ; we compute $C_\ell(z_i^{\text{term}}, z_j^{\text{all}})$ and then add its transpose,

$$\frac{\partial C_\ell^{AB}(z_i, z_j)}{\partial \varepsilon_{\text{term}}} = C_\ell^{AB}(z_i^{\text{term}}, z_j^{\text{all}}) + C_\ell^{AB}(z_i^{\text{all}}, z_j^{\text{term}}). \quad (\text{A9})$$
